Abstract

Extreme coastal inundation associated with the 2004 Indian Ocean and 1945 Makran tsunamigenic–earthquakes highlight the risk of tsunamis to coastlines of the northern Oman Sea. Foraminifera have been used as indicators of paleotsunamis in the past where allochthonous tests, found in low–energy environments such as in coastal lagoons, ponds, and marshes, indicate marine overwash. In this study, we constrain the modern distributions of foraminifera from coastal Iran so that they may be used to identify and interpret (e.g. assess provenance) paleotsunami deposits in the geologic record. We collected surface sediment samples from sixteen sites within the study area from Chabahar to Gawater Bays on the Makran coast of Iran, selecting locations impacted by the 1945 Makran tsunami. Foraminifera obtained from these locations are dominated by supratidal, intertidal, and subtidal species, with minor abundances of planktic taxa. Samples collected from study locations are characterized by abundances of iron–stained and heavily corroded (e.g. edge rounded and pitted) individuals. Cluster analysis was used to determine three foraminiferal assemblages within the Makran coastal zone: subtidal, intertidal and supratidal. Characterizing modern distributions of foraminifera along the Makran coast of Iran will aid in identifying the provenance of older overwash deposits previously identified in this region.

Keywords: Foraminifera, Coastal Sediments, Paleotsunami, Makran, Oman Sea.

Introduction

Paleotsunami deposits preserved in the geological record provide a means of extending the known record of events from several hundreds of years to several thousands of years, capturing both the frequent and infrequent, but higher magnitude, events. The majority of studies on paleotsunami deposits have been conducted in temperate regions, with few studies in tropical regions, and even fewer in arid environments. Although the 2004 Indian Ocean tsunami and the 1945 Makran tsunami demonstrate the tsunami risk to the Makran area of Iran and adjacent coastlines, this area has been the subject of few published (Mokhtari *et al.*, 2008; Shah–Hosseini *et al.*, 2011; Hamzeh *et al.*, 2013; Okal *et al.*, 2015) paleotsunami studies. Donato *et al.*, (2008, 2009) and Pilarczyk *et al.*, (2011, 2012) investigated shell layers, grain size distributions, and foraminifera, respectively, from the 1945 Makran tsunami in Sur Lagoon (coast of Oman). Numerical studies have also been done to assess the tsunami risk of the Makran and adjacent coastlines (Mokhtari *et al.*, 2008; Heidarzadeh *et al.*, 2008a, 2009; Okal & Synolakis, 2008; Okal *et al.*, 2015; Jaiswal *et al.*, 2009; Shah–Hosseini *et al.*, 2011; Payande *et al.*, 2015).

Foraminifera are useful indicators of tsunami and

storm overwash because they identify allochthonous sediments in marginal marine environments such as coastal lagoons, ponds, and marshes. Studies that employ foraminifera to identify marine overwash are abundant in temperate regions (e.g. Hippensteel *et al.*, 2000; Scott *et al.*, 2003; Hawkes & Horton, 2012; Pilarczyk *et al.*, 2012), with few studies in tropical regions (Sugawara *et al.*, 2009; Sieh *et al.*, 2015; Goff *et al.*, 2011), and even fewer in arid environments (e.g. Dominey–Howes *et al.*, 2006; Pilarczyk & Reinhardt, 2012). Tsunami deposits in arid environments are generally poorly preserved due to high rates of deflation. The accelerated post–depositional change in arid environments results in difficulty in identifying and interpreting overwash deposits. Foraminifera help in this regard because their tests preserve well in the geologic record and their presence indicates a marine origin (Pilarczyk *et al.*, 2014).

Studies that document the modern spatial distribution of foraminifera can be used as a basis for comparison with overwash sediments to assess sediment provenance (Kosciuch *et al.*, 2018; Phat *et al.*, 2018). Modern distributions of various subenvironments found in western India, Oman, Iran, and the Persian Gulf have been extensively

documented (e.g. Murray, 1965, 1966a, b, c; Reddy & Rao, 1984; EL-Nakhal, 1990; Nigam & Khare, 1995; Cherif *et al.*, 1997; Lezine *et al.*, 2002; Bahalla *et al.*, 2007; Moghaddasi *et al.*, 2008; Ghosh *et al.*, 2009; Pilarczyk *et al.*, 2011).

Historical records mention several tsunamis that have impacted coastlines around the northern Arabian Sea (e.g. events at 325 BC, 1483, 1765, 1851, etc.; Ambraseys & Melville, 1982; Heidarzadeh *et al.*, 2008a, 2008b; Heidarzadeh *et al.*, 2009), including at least six events that had a magnitude greater than 8.0. On 28 November 1945, a Mw 8.1 subduction zone earthquake occurred approximately 300 km west of Karachi, Pakistan, resulting in a tsunami with wave heights ranging from 2 to 13 m (Ambresys & Melville, 1982; Byrne *et al.*, 1992; Pararas-Carayannis, 2006). Tsunami run-up heights along the Iranian coast from this event were variable, ranging from 0.5 m in Gordim Bay near the town of Konarak to 10 m in Gawater Bay near the border with Pakistan (Hamzeh *et al.*, 2013). Death tolls associated with the 1945 tsunami were low along the Iranian coast due to the low population density that was limited to small fishing villages (e.g. Chabahar, Lipar, Beris, and Pasabandar).

In this study, we document the surface distribution of foraminifera in coastal sediments along the Iranian coast between Chabahar and Gawater Bays and assess whether they can be used as indicators of tsunami overwash in this region. The modern distribution of foraminifera along the

Chabahar Bay coastline is mapped in order to determine which species and taphonomic characters (i.e., surface condition of individual foraminifera) will be most useful in detecting and interpreting overwash deposition.

Regional setting

The northwestern Makran coast is vulnerable to earthquakes and tsunamis as a result of its proximity to the Makran Subduction Zone. The coastline stretches a distance of approximately 1000 km between Iran and Pakistan, from the Strait of Hormuz in the west to Karachi, Pakistan in the east. This region is part of the accretionary wedge of the Makran Subduction Zone, formed by the subduction of the Arabian Plate under the Eurasian Plate (Byrne *et al.*, 1992; Regard *et al.*, 2005). The Makran coast is marked by a series of prominent headlands separated by bays. Further inland, uplifted Plio-Pleistocene marine terraces and sandstones are undergoing intensive erosion under arid conditions (Reyss *et al.*, 1998). The coastline has been prograding since the mid-Holocene, owing to both the slight tectonic uplift and marine and alluvial sedimentation (Reyss *et al.*, 1998).

The Iranian part of the Makran coast is a subtropical arid region, extending for approximately 640 km from Bandar Abbas in the Strait of Hormuz to Gawater on the Iranian-Pakistani border. However, this study focuses on the area between Chabahar and Gawater Bays (Fig. 1).

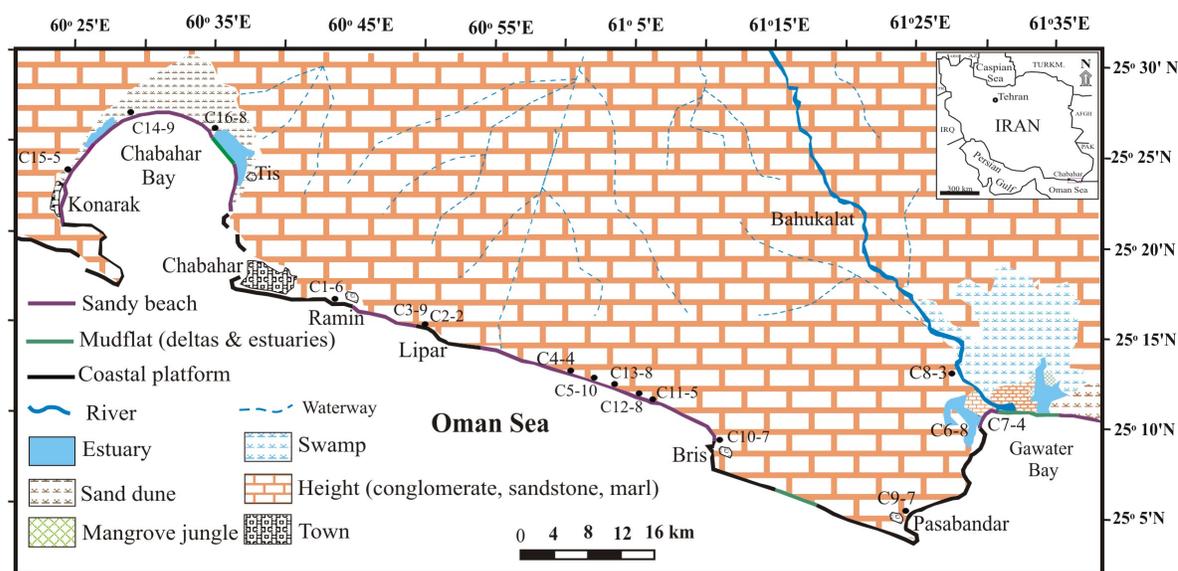

Figure 1. Geomorphology map (modified from Hamzeh *et al.*, 2014) and locations of the study sites from Chabahar to Gawater Bay, on the Iranian Makran coast, Oman Sea.

The Iranian coast along the Oman Sea (Sistan and Baluchestan Province) can be divided into three main geomorphologic features: coastal platforms (terraces), sand beaches, and mud flats (deltas and estuaries) (Hamzeh *et al.*, 2014; Fig. 1). Coastal platforms are the most frequent landform in the area and are formed by the aforementioned tectonic uplift of coastal Makran and the effect of waves upon the shoreline. Onshore sandy dunes are common features in the study area. Within the bays, paleobeaches are seen as sand bands parallel to the modern shoreline. Deltas and estuaries are formed by sedimentation of seasonal streams, with mangroves formed in some estuaries, such as at Bahukalat, and in parts of Chabahar Bay (Fig. 1). In general, the geomorphology of coastal Makran is closely controlled by the coast's structural pattern, weather conditions, and geological facies (Hamzeh *et al.*, 2013).

Materials and Methods

Sixteen sites (see Tables 1–3) along the Iranian coast of the Oman Sea were investigated for foraminiferal content. The sites are located between Chabahar Bay and the middle part of Gawater Bay at the Iran–Pakistan border (Fig. 1) and include coastal platforms, sandy beaches, and mudflats deposited in the tidal–channel levee, intertidal, and subtidal environments (Tables 1–3). From the study sites, sixteen cores (core depths 32–143 cm) were collected from sandy beaches and mudflats (Figs. 1–5). In total, 109 sediment samples were collected from these cores and 16 surface samples (collected from the upper 2 cm of sediment) were investigated for granulometry (grain–size) and their foraminifera distributions (Tables 1–3).

Samples for foraminiferal analysis were sieved at 63 μm , dry split to obtain counts of approximately 300 specimens, and examined under a microscope. Specimens were picked by hand and placed on slides for identification and imaging. Taxonomy followed Debenay (2012), Loeblich & Tapan (1988), Ellis and Messina's Foraminifera Catalogue (2010), and other previous studies (*e.g.* Moghaddasi *et al.*, 2008; Debenay, 2001; Murray, 1965, 1966a, 1966b; Nigam & Khare, 1995; Akimoto *et al.*, 2002; Hottinger *et al.*, 1993; Cimerman & Langer, 1991; Bhalla *et al.*, 2007). The taphonomic condition of each individual foraminifer was assessed and categorized according to the observation of iron–staining and degree of corrosion in three levels minor, moderate and

maximum (Fig. 6). A scanning–electron microscope (SEM) located at the Canadian Centre for Electron Microscopy at McMaster University was used to take photographs of foraminiferal specimens.

Partitioning Around Medoid (PAM) cluster analysis (Kaufman & Rousseeuw, 1990) was then used to identify biofacies within the modern environment at Chabahar and Gawater Bays. The methods of Pilarczyk *et al.* (2016) and Kosciuch *et al.* (2018) were followed, where foraminiferal counts (iron stained versus unstained foraminifera) were first converted to relative abundances, and then standardized using z -scores. PAM cluster analysis produces silhouette widths that indicate how appropriately a given sample is clustered. A silhouette width of -1 indicates an incorrect classification, whereas a silhouette width of 1 indicates perfect assignment to the appropriate cluster. The number of biofacies at our study sites was determined by selecting the cluster scenario that produced the highest average silhouette width.

Results

Within the sampling area, three major sedimentological sub–environments exist: sandy beaches, mudflats and tidal channels. Foraminifera collected from these subenvironments were characterized by high abundances of iron staining and/or corrosion. Comprehensive data on the study sites including location, sediment, grains/size, foraminifera, corrosion etc. are showing in tables 1–3.

Distribution of foraminifera

Sixteen surface samples were selected for foraminiferal analysis. All samples contained abundant foraminifera (85–100%) and a significant percentage of the specimens had iron stained tests (Figs. 7–10; Tables 1–3). The foraminifera identified in the samples belong to 38 genera and 41 species (Fig. 11). The most abundant species include *Ammonia convexa* (15–68%), *Elphidium craticulatum* (6–26%), *Assilina ammonoides* (17–31%) and miliolids (3–19%). Apart from foraminifera, other invertebrates, including ostracods, gastropods, bivalves, and sponges were also recovered from the samples.

Sandy beach subenvironment

Sandy beaches are composed of poorly to well sorted, fine to very coarse sand and are interpreted as intertidal in nature (Samples C1–6, C9–7, C13–

8, and C16–8). The most abundant foraminiferal species recovered from these samples were *Ammonia convexa*, *Assilina ammonoides*, *Elphidium craticulatum* and various miliolids. Other recorded invertebrates included ostracods,

gastropods, and sponges. Overall, 47–60% of foraminiferal tests show iron staining, with maximum, moderate, and minor levels of corrosion seen in a range of 0–33%, 20–50%, and 17–63% of specimens, respectively.

Small fragments	57.9%	63.2%	0%	50.53%	36.64%

Among the shell fragments (foraminifera and other fauna), large fragments account for 39–61% of the material, and small fragments making up 38–61% of specimens (Tables 1–3).

Mudflat subenvironment

Mudflats, which include delta and estuarine sites, yielded sediment samples composed of poorly to well sorted, fine silt and clay. These sites are subtidal and tend to be related to tidal channel levee

environments (Samples C6–8, C7–4, C8–3, C14–9, and C15–5). The most abundant foraminiferal species in these samples are *Ammonia convexa*, *Assilina ammonoides*, *Asterorotalia galimardi*, *Elphidium craticulatum*, *Pararotalia nipponica*, *Spiroplectinella* sp., and various miliolids. Besides foraminifera, ostracods, gastropods, bivalves, and sponges are also seen in these samples. Overall, 14–36% of foraminifera in mudflat samples have iron stained tests, with maximum, moderate, and minor

levels of corrosion recorded in a range of 0–22%, 0–56%, and 22–100% of specimens, respectively. Among the shell fragments (foraminifera and other

fauna), large fragments account for 22–100% of the material, with small fragments making up 0–88% of recovered specimens (Tables 1–3).

Tidal channel subenvironment

Tidal channels yielded sediments composed of medium to well sorted, fine to very coarse sand (Sample C2-2, C3-9, C4-4, C5-10, C10-7, C11-5,

and C12-8). This sub-environment is predominantly supratidal in nature, but, like the mudflats, is also linked to tidal channel levee environments. The most abundant foraminifera in

these samples are *Ammonia convexa*, *Ammonia aoteana*, *Assilina ammonoides*, *Elphidium craticulatum*, *Lenticulina* sp., and various miliolids. Apart from the foraminifera, ostracods, gastropods and sponges are also recovered from these sites. Overall, 31–79% of foraminifera in tidal channel samples have iron stained tests, with maximum, moderate, and minor levels of corrosion recorded in a range of 0–53%, 19–47%, and 26–80% of specimens, respectively. Among the shell fragments (foraminifera and other fauna), large fragments account for 26–62% of the material, with small fragments making up 37–74% of recovered specimens (Tables 1–3).

Cluster analysis

Partitioning Around Medoids (PAM) cluster analysis identified three biofacies within the study area (Fig. 12; tables 1–3) that have a collective average silhouette width of 0.68: BF₁ (intertidal environment; Average silhouette width = 0.82), BF₂ (supratidal environment; Average silhouette width = 0.65), and BF₃ (subtidal environment; Average silhouette width = 0.63). BF₁ is characterized by sandy beaches, high abundances of heavily corroded individuals (47–60%), and high abundances of *Ammonia convexa*, *Assilina ammonoides*, and *Elphidium craticulatum* (samples C1–6, C9–7, C13–8, and C16–8). BF₂ is

characterized by tidal channels, high abundances of iron-stained individuals (31–79%), and high abundances of *Ammonia aoteana*, and *Lenticulina* sp. (samples C2–2, C3–9, C4–4, C5–10, C10–7, C11–5, and C12–8). BF₃ is characterized by mudflat environments (deltas and estuaries), low abundances of iron-stained individuals (14–36%), high abundances of moderately corroded individuals and high abundances of the foraminifera *Ammonia convexa*, *Asterorotalia galimardi*, *Elphidium craticulatum*, *Pararotalia nipponica*, and *Spiroplectinella* sp. (samples C6–8, C7–4, C8–3, C14–9, and C15–5).

As mentioned above, samples collected from supratidal locations show an average of maximum iron staining and corrosion than samples collected from intertidal and subtidal locations. However, for all samples, a significant percentage of foraminifera (14–79%) show iron staining and corrosion and as a whole, the range abundances of corroded specimens are 0–53% showing maximum corrosion, 0–56% having moderate corrosion and 17–100% showing minimum corrosion. Among the shell fragments, large fragments make up 26–100% of specimens, with small fragments forming 0–74% of the material.

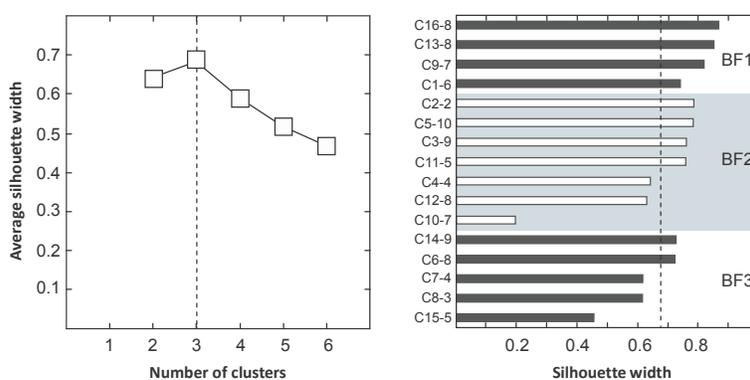

Figure 12. Results of PAM cluster analysis showing three biofacies. a) Average silhouette width for 2 - 6 cluster scenarios. The highest average silhouette width (representing the strongest structure) for each cluster is indicated by a hashed line. b) Silhouette plots of stained and non-stained foraminifera divided into three clusters (highest average silhouette width). Grey and white areas differentiate between clusters and the average silhouette width is indicated by a dashed line.

Discussion

Okal *et al.* (2015) report the result of a 2010 survey of the effects on the Iranian coastline of the tsunami which followed the earthquake of 28 November 1945 ($M_0 = 2.8 \times 10^{28}$ dyn cm; $M_w = 8.2$) which accompanied with the tsunami waves, resulted from an ancillary phenomenon, such as a landslide operated by the earthquake. Also, Shah–Hosseini *et al.* (2011) reported 58 coastal boulders attesting to large waves along the rocky coast of Iranian Makran from Chahbahar to Lipar (Fig. 1) which are mostly rectangular and composed of biogenic calcarenite deriving from the present coastal platform. They have morphological features include supratidal karstic pools, sharp broken edges and fractures, and some of them contain boreholes and

shells of marine bivalves, suggesting detachment and transportation from the subtidal zone (Shah–Hosseini *et al.*, 2011). The boulders, weighing up to 18 t, were found up to 6 m above present mean sea level and up to 40 m from the present shoreline. Shah–Hosseini *et al.* (2011) believe tsunami wave height of 4 m is enough to detach all the boulders from the rocky coast and transport them inland, and a tsunamigenic origin for boulder deposits is most possible which probably generated by large earthquakes at the Makran subduction zone.

In addition to the issues discussed above, the uppermost coastal sediments of the Oman Sea (Chahbahar Bay to the middle part of Gawater Bay) contain a significant percentage of foraminifera which are mostly corroded and show iron staining, and could be used as an overwash indicator in

coastal and lagoonal environments. These sediments indicate an event layer which can be either storm- or tsunami generated. The presence of heavy boulders in the coast of Iranian Makran which exclusively found in the tsunami deposit could be confirmed a tsunami event.

The abundance and significant foraminiferal species in the studied samples are *Ammonia convexa*, *A. aoteana*, *A. tepida*, *A. inflata*, *Amphistegina lessonii*, *Assilina ammonoides*, *Asterorotalia galimardi*, *Elphidium craticulatum*, *E. crispum*, *Pararotalia nipponica*, *Spiroplectinella* sp., *Lenticulina* sp., planktic species (e.g. *Globigerinoides*, *Globigerinita*, *Globorotalia*) and various miliolids. The most useful taxa for recognizing a marine incursion (e.g. tsunami or storm) are abundant *Amphistegina* spp., *Ammonia inflata*, *Elphidium advenum* and planktic species, with these groups expected to be highly concentrated through transport and sorting within an event bed.

Foraminiferal taphonomy has previously been used as an overwash indicator in coastal environments (Pilarczyk et al., 2014; Rubin et al., 2017; Kosciuch et al., 2018). The abundance of miliolids, *Ammonia tepida*, *Ammonia parkinsoniana*, and *Elphidium gerthi* suggests these taxa are the dominant foraminifera living in the coastal bay, an interpretation consistent with other similar coastal environments (e.g. Murray, 1991; Debenay et al., 2001; Lezine et al., 2002; Ghosh et al., 2009).

Most of the taxa listed in this study are considered indicative of coastal bay and lagoonal environments. This idea is consistent with similar coastal environments where these taxa also dominate assemblages (e.g. Murray, 1991; Debenay et al., 2001, Debenay, 2012; Lezine et al., 2002; Ghosh et al., 2009).

In this study, the abundances foraminifera such as *Amphistegina*, *Ammonia*, *Elphidium*, and planktics which are predominantly found in the shallow marine area are useful taxa for recognizing a marine overwash (e.g. tsunami or storm). The existence of iron staining on foraminiferal tests and the observed percentages of corrosion may be related to upwelling with a marine incursion such as tsunami or storm, and the effects of erosion and corrosion under oxidizing conditions. The foraminiferal analysis was able to distinguish the tsunami unit based on shell taphonomy and particle

size analysis. Therefore, foraminifera appear to be the most useful parameters for assessing overwash events along the Iranian coast.

Conclusions

Sediments studied from the Iranian coast of the Oman Sea appear to have been transported from the shallow marine area into the modern coastal platforms, sandy beaches, and mudflats by a marine incursion such as a tsunami or storm. This transport of sediments is supported by the foraminiferal results. In this study, the surface distribution of foraminifera was examined in various sub-environments of the Makran coast between Chabahar and Gawater Bays, Oman Sea. These foraminifera obtained from these locations are dominated by subtidal, intertidal, and supratidal species, with minor abundances of planktic taxa, and showing iron staining and corrosion. By PAM cluster analysis were determined three foraminiferal assemblages existing within the Makran coastal zone: subtidal, intertidal, and supratidal. Samples collected from intertidal locations (BF₁) are characterized by high abundances of heavily corroded individuals, whereas samples collected from supratidal locations (BF₂) are dominated by high abundances of iron-stained and heavily corroded individuals, and samples collected from subtidal locations (BF₃) are characterized by low abundances of iron-stained individuals and high abundances of moderately corroded individuals. This suggests that analyzing modern distributions of fossil foraminifera in surface samples will enable an improved interpretation of the 1945 deposit.

Acknowledgments

The present research has been carried out at the School of Geography and Earth Sciences, McMaster University, Canada which is gratefully acknowledged. The authors would like to deeply thank the Iranian National Institute for Oceanography and Atmospheric Science (INIOAS)–Gulf of Oman and Indian Ocean Research Center (Chabahar) for logistic support in the field, M.A. Hamzeh (Graduate University of Advanced Technology & INIOAS), H. and M. Afarin (INIOAS) for their assistance in the field, A. Naderi–Beni (INIOAS), M. Shah–Hosseini (Aix–Marseille University), and D. Jahani (Islamic Azad University, North Tehran Branch) for their useful comments and suggestions, J. Murray (University of Southampton) and J.P. Debenay (University of Angers) for reviewing and valuable suggestions on

foraminiferal samples, and S.K. Martin (Geological Survey of Western Australia), A. Matsuoka (Niigata University) and two anonymous reviewers for providing constructive comments on the manuscript. The photomicrographs of foraminifers

were obtained by scanning electron microscope (SEM) with the kind help of G. de Silveira at the Canadian for Electron Microscopy, McMaster University, which we gratefully acknowledge.
